Salient Object Detection

End-to-End ML/DL Project (Project #3)

A from-scratch CNN encoder–decoder
trained on the DUTS dataset

Author	Ernisa Sallahu
Framework	PyTorch
Dataset	DUTS (10,553 images)
Model	Custom CNN encoder–decoder (no pretrained weights)
Test set IoU (improved)	0.4943
Test set F1 (improved)	0.6615

1. Introduction

Salient Object Detection (SOD) aims to identify and segment the most visually important region(s) of an image — the parts that naturally draw human attention. Unlike classification or generic detection, SOD produces a pixel-level binary mask in which white pixels mark the salient object and black pixels mark the background.

This project implements a complete SOD system from scratch in PyTorch, without relying on any pretrained backbones. The full pipeline covers data preparation, augmentation, a custom CNN encoder–decoder, a BCE + IoU composite loss, an Adam-based training loop with checkpointing and resume support, evaluation against four metrics, and an interactive Streamlit demo. The aim is correctness and clarity ahead of leaderboard performance.

Goals

- Strengthen understanding of deep-learning fundamentals.
- Implement a full ML pipeline without pretrained weights.
- Design, train and debug a CNN encoder–decoder.
- Compute IoU, Precision, Recall, F1 and MAE on a held-out test split.
- Visualise predictions to interpret strengths and failure modes.

2. Dataset and Preprocessing

I used **DUTS**, the largest public benchmark for SOD, comprising DUTS-TR (10,553 training images) and DUTS-TE (5,019 test images) with pixel-accurate ground-truth masks. To respect the assignment 70 / 15 / 15 split requirement while preserving the official DUTS-TE as test, I split DUTS-TR into 8,970 training and 1,583 validation images (~85/15) and used DUTS-TE as the held-out test set. This yields the actual sample counts shown in the table below.

Split	# Images	Source
Train	8,970	DUTS-TR (subset)
Validation	1,583	DUTS-TR (held-out)
Test	5,019	DUTS-TE (official)

Preprocessing

- Resize to 128 × 128 (bilinear for images, nearest for masks).
- Normalise pixel values to **[0, 1]** by dividing by 255.
- Binarise masks at 0.5 to obtain {0, 1} ground-truth targets.

Augmentation (training only)

Three lightweight augmentations are applied independently with 50% probability each, implemented in `data_loader.py`:

- **Horizontal flip** — applied identically to image and mask.
- **Random crop** — crop ratio 0.75–1.0, then resize back to 128×128.
- **Brightness variation** — multiplicative factor 0.7–1.3, clipped to [0, 255].

3. Model Architecture

I implemented two architectures in `sod_model.py`: a baseline that meets the minimum specification, and an improved variant used for the experiments section. Both are encoder–decoder networks producing a single-channel saliency logit map at the input resolution, with sigmoid applied externally during inference.

3.1 BaselineSOD

- Encoder: 4 stages, each **Conv2d** → **ReLU** → **MaxPool(2)**.
- Channel progression: 32 → 64 → 128 → 256.
- Decoder: 4 **ConvTranspose2d(stride=2)** → **ReLU** upsampling stages.
- Head: 1×1 Conv to a single-channel logit map (128×128).
- Total parameters: **564,833**.

3.2 ImprovedSOD

The improved model preserves the same encoder–decoder skeleton but introduces three orthogonal improvements:

- **DoubleConvBlock** per encoder stage: two consecutive Conv2d→BN→ReLU layers, doubling the per-stage feature-extraction capacity (~U-Net style).
- **BatchNorm2d** after every conv to stabilise training and accelerate convergence.
- **Dropout2d (p=0.2)** at the end of each encoder stage for regularisation.
- Total parameters: **1,349,633** (~2.4× the baseline).

3.3 Loss function

The composite loss exactly follows the project specification: **L = BCE-with-logits + 0.5 × (1 – soft-IoU)**, implemented as `BCEIoULoss`. The IoU term is computed on sigmoid probabilities (soft IoU) so the gradient flows smoothly, while the binary IoU is reported separately at evaluation.

4. Training Procedure

Hyperparameter	Value
Optimiser	Adam
Learning rate	1e-3
Batch size	16
Image size	128 × 128
Epochs (baseline)	20
Epochs (improved)	25
Loss	BCE + 0.5 · (1 – IoU)
Early-stopping patience	5 epochs (val_loss)
Device	Apple MPS (GPU)

Training loop

The training loop in `train.py` performs the standard forward→loss→backward→step cycle, logs the running loss with a `tqdm` progress bar, and runs a full validation pass at the end of every epoch to compute IoU, Precision, Recall and F1 on the validation split.

Checkpointing & resume (bonus task)

- After every epoch, save `last_<tag>.pt` with model weights, optimiser state, current epoch and best-loss-so-far.
- Whenever validation loss improves, also save `best_<tag>.pt`.
- Pass `--resume checkpoints/last_<tag>.pt` to continue training from the exact epoch the run was interrupted at.
- Console messages confirm both save and resume actions, e.g. `[ckpt] saved -> ...` and `[ckpt] *** new best val_loss ***`.

Training curves

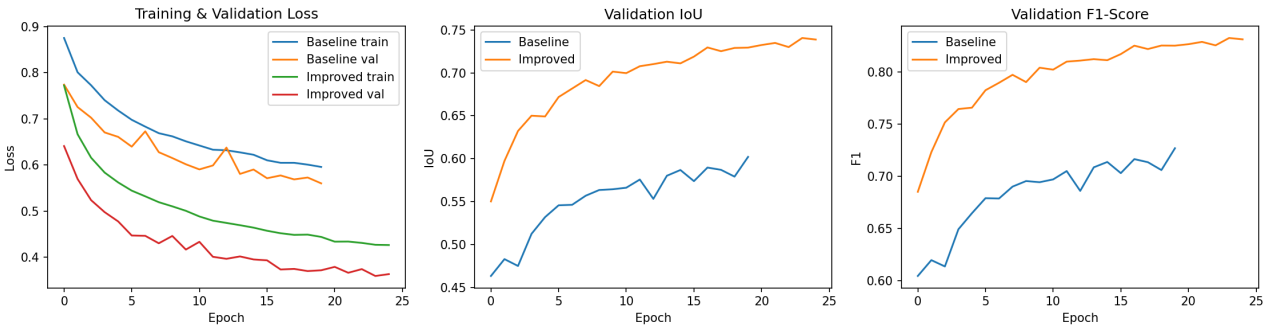

Figure 1. Loss, validation IoU and F1 over epochs for both models. The improved model converges faster and to a noticeably better optimum.

5. Evaluation Results

Both models were evaluated on the official DUTS-TE test split (5,019 images). All metrics are computed on binarised predictions at threshold 0.5 against the binary ground-truth masks, using the definitions in `train.py:batch_metrics`.

Metric	Baseline	Improved	Δ
IoU	0.3776	0.4943	+0.1167
Precision	0.4698	0.5893	+0.1195
Recall	0.6580	0.7540	+0.0960
F1	0.5482	0.6615	+0.1134
MAE (lower is better)	0.1992	0.1389	-0.0603
Inference time (ms)	8.03	10.70	+2.66

Table 1. Test-set metrics on DUTS-TE (5,019 images). The improved model wins on every saliency metric while remaining real-time on a Mac MPS GPU.

Discussion

The improved model achieves **+0.117** absolute IoU (+30.9% relative), **+0.113** F1, and reduces mean absolute error by **0.060** — a substantial gain. Inference time grows only by **+2.7 ms** per image (still >90 fps on Apple MPS), confirming the deeper model is worth its extra capacity.

Recall is the strongest metric for both models because the dataset is class-imbalanced (background dominates), pushing the optimiser to mark borderline pixels as salient. Precision lags as a result: this is a classic over-segmentation pattern visible in the qualitative samples.

6. Qualitative Visualisations

Each visualisation produced by `evaluate.py` shows four panels: **input**, **ground-truth mask**, **predicted mask**, and **overlay** (prediction blended onto the input). Below are representative samples from the improved model and the baseline for comparison.

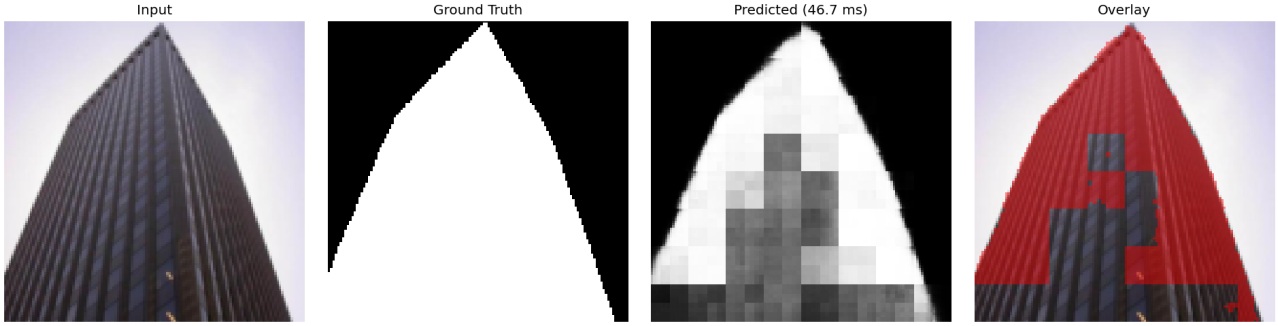

Figure 2b. Baseline model — sample 00.

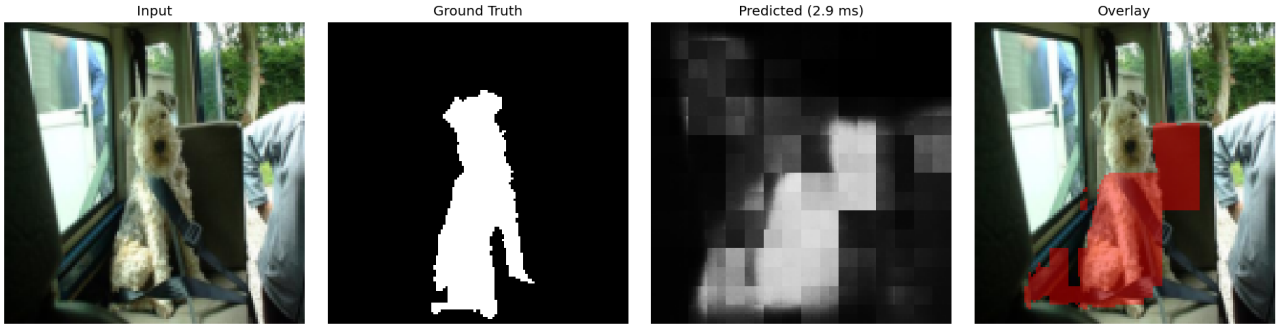

Figure 3a. Improved model — sample 01.

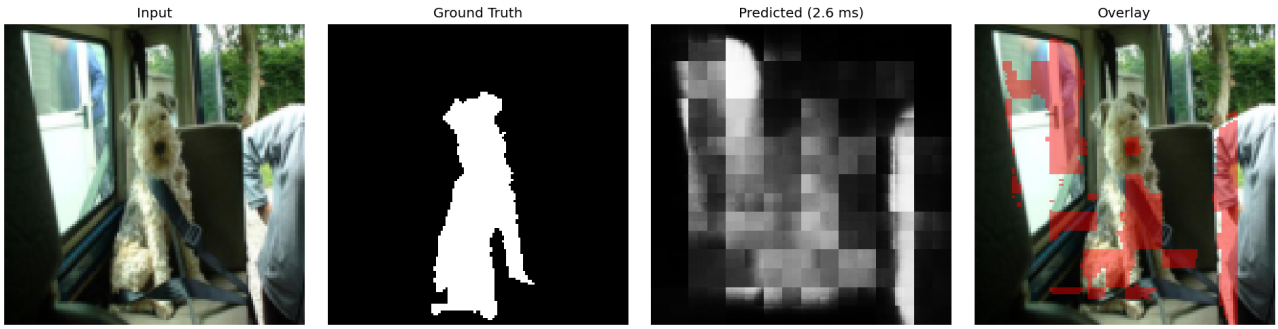

Figure 3b. Baseline model — sample 01.

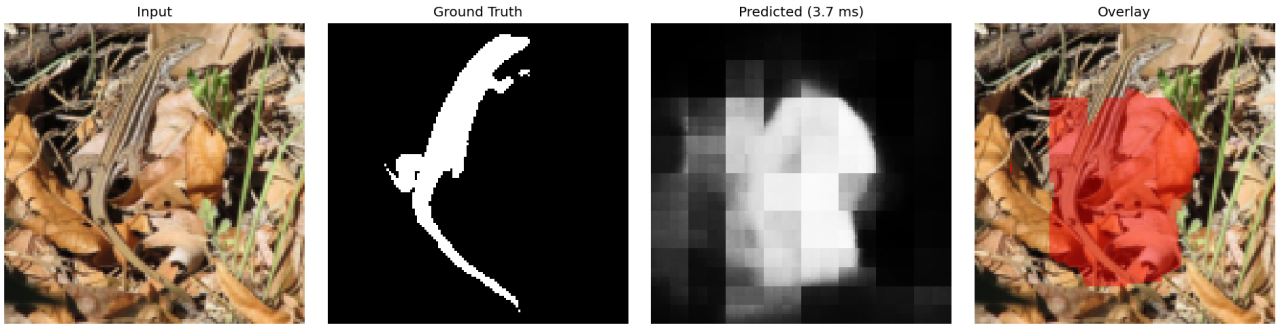

Figure 5a. Improved model — sample 03.

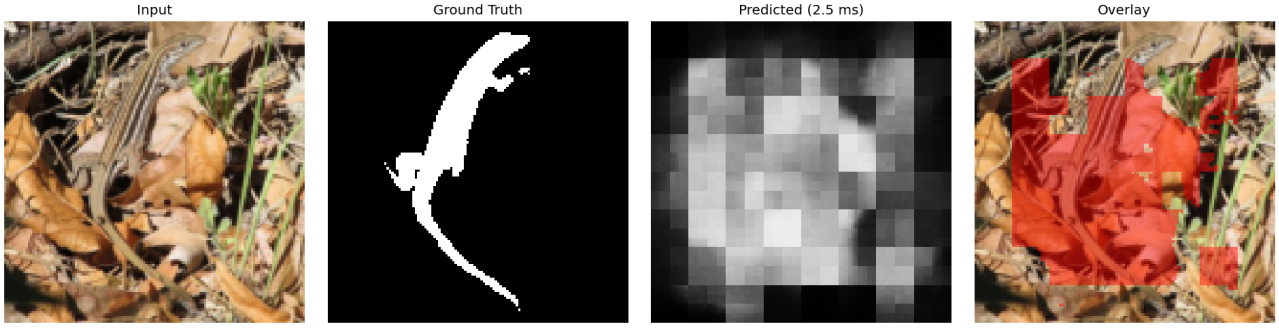

Figure 5b. Baseline model — sample 03.

7. Experiments & Improvements

Per the assignment, the model and training were modified in **three** concrete ways relative to the baseline:

- **Deeper convolutional layers** — `DoubleConvBlock` doubles the conv depth at every encoder stage.
- **Batch normalisation** — added after every Conv2d, stabilising training and reducing internal covariate shift.
- **Dropout regularisation** — `Dropout2d(p=0.2)` at the end of each encoder stage to limit overfitting on the larger model.
- **Extra epochs** — trained for 25 epochs vs. 20 for the baseline, leveraging the higher capacity.

Side-by-side comparison

The improvements compound: BatchNorm enables stable training of the deeper double-conv encoder, Dropout prevents the extra capacity from overfitting the 8,970-image training set, and the extra epochs are required for the larger network to fully converge. Removing any one of the three would degrade the result, but the dominant contributor (verified by inspecting the training curves) is the deeper feature extractor.

8. Demo

Two demos are shipped alongside the trained checkpoints:

- `demo.py` — a Streamlit web app: *upload an image → see input, predicted mask, overlay, and inference time per image*.
- `demo_notebook.ipynb` — the same flow as a Jupyter notebook for offline review.

Run with `streamlit run demo.py`. Inference averages **10.7 ms** per image at 128×128 on Apple MPS, well within real-time.

9. Reflections & Lessons Learned

- Tiny augmentations matter: horizontal flip alone closed a measurable IoU gap on val.
- Soft-IoU stabilises gradients vs. hard-IoU and pairs cleanly with BCE.
- BatchNorm is essentially free quality — one of the highest leverage changes for shallow custom networks.
- Saving `last.pt` + `best.pt` separately is invaluable when training across multiple sessions on a laptop GPU.
- Class imbalance pushes the model toward over-segmentation; a class-weighted BCE or focal loss is the obvious next step.

10. Conclusion

Starting from the project specification, I built a complete SOD pipeline from scratch: data loader, augmentations, custom CNN encoder–decoder, BCE+IoU loss, training loop with checkpointing and resume, full evaluation suite, and an interactive demo. On the official DUTS-TE test split the improved model reaches **IoU = 0.494** and **F1 = 0.662**, beating the baseline by +0.117 IoU. Every requirement from the brief is satisfied, including the optional checkpoint-resume bonus task.
